**Abstract**

Toxoplasmosis is still one of the most common parasitic infections in the world, although in Europe improvements in hygiene and the introduction of ‘total’ indoor farming in livestock production have rapidly diminished the problem during the past decades. As a result of public dislike, however, introduction of alternative and more acceptable animal-friendly livestock production systems including outdoor access are gaining ground. Potentially these systems can lead to increased prevalence of certain zoonotic diseases, including Toxoplasmosis. To retain prevalence of this disease in humans at current levels, emphasis should be on disease control at farm-level. This article provides an analysis of various risk factors for farm animals to get infected with *Toxoplasma gondii*. Access of cats to the farm premises, the use of compost and goat whey, and rodent control were identified as possible risk factors that should be addressed. Consumers should be aware of the fact that *Toxoplasma* infection, besides through meat, can also be caused by the uptake of contaminated water, soil, fruit and vegetables.

*Additional keywords:* organic production, risk factors, rodents, parasitic infections

**Introduction**

Toxoplasmosis, caused by *Toxoplasma gondii*, is currently the most prevalent parasitic zoonotic disease throughout the world (Tenter *et al*., 2000). It is an important cause of abortion in humans and livestock (sheep) and was recently shown to be the third cause of death following food-borne illnesses (Mead *et al*., 1999). In humans it is further known to cause mental retardation, encephalitis and blindness. Although not fatal, ocular Toxoplasmosis is probably the most frequently occurring complication of this
disease (Holland, 2003) whereby eventually 24% of the affected persons become blind (Bosch-Driessen et al., 2002). Over the years a large number of anti-parasitic drugs have been developed to treat patients with Toxoplasmosis, with good results under certain conditions. However, the drugs developed so far were not always effective in the treatment of ocular Toxoplasmosis (Stanford et al., 2003). So at present, prevention of *Toxoplasma* infection is the only strategy to combat the blinding complications of Toxoplasmosis. Since meat consumption is one of the main risk factors, prevention should also be aimed at livestock production.

Over the past decades animal farming in Western Europe has drastically changed. Some of these changes are not in favour of animal welfare and have led to alternative production systems such as organic animal husbandry. At this moment, the impact of these animal-friendly production systems on certain zoonotic diseases such as Toxoplasmosis is not clear. In this short review we shall discuss risk factors for an animal to become infected with *Toxoplasma* and present a risk analysis with a number of control points to limit the on-farm risk.

**Parasitology**

*Toxoplasma gondii* is a ubiquitous protozoan parasite capable of infecting virtually all warm-blooded vertebrates in the world. It is an obligate intracellular organism belonging to the Coccidian family. Three strains of *Toxoplasma gondii* have been defined, (type I, type II and type III), of which type I is extremely virulent for mice and type II has been associated with the majority of Toxoplasmosis cases in AIDS patients (Boothroyd & Grigg, 2002; Klaren & Kijlstra, 2002). Type III is present in animals and has been detected in AIDS patients, but does not seem to be associated with ocular Toxoplasmosis (Boothroyd & Grigg, 2002).

The parasite has a complex life cycle whereby Felidae (cats) function as the definitive host, i.e., the sexual part of the life cycle takes place in these animals. Fusion of gametocytes and zygotes takes place in the gut of catlike animals leading to the formation of eggs (oocysts). Cats have been shown to shed millions of oocysts via their faeces into the environment during a period of a few weeks (Dubey, 2001). Oocysts must mature (sporulate) for 1–5 days to become infective for other hosts. Sporulated oocysts can remain in a moist environment for some years (Dubey & Beattie, 1988) since they are resistant to a large number of threats such as heat and cold. Further prolongation of the oocyst’s lifetime may be due to the uptake by other organisms in the soil or water. Some West European countries (e.g. the Netherlands, Belgium, United Kingdom, Germany and Denmark) have optimum climatic conditions for a parasite like *Toxoplasma gondii* to thrive, because of their moist summers and generally temperate winters. As they also have a large population of pet cats, it is not remarkable that Toxoplasmosis is now recognized as a serious health problem in these countries.

When an intermediate host ingests a sporulated *Toxoplasma* oocyst the parasite transforms into a stage called the tachyzoite. Tachyzoites can infect virtually any nucleated cell type, although a tropism for certain cell types (for instance retinal vascular endothelial cells) has been reported (Smith et al., 2004). After invading a cell, the
tachyzoites can rapidly divide and after death of the host cell they will invade adjacent cells or – after traveling through the blood stream – attach to cells elsewhere in the body. The tachyzoite stage can transform into a slowly dividing bradyzoite. This stage of the parasite is able to form a cyst wall around a large family of dividing parasites, thereby protecting the parasite against the mounting immune response of the host. The stage differentiation from tachyzoite to bradyzoite is thought to be triggered by certain cytokines of the cellular host immune response (Klaren & Kijlstra, 2002). The parasite can remain dormant in its encysted stage whereby release of parasites from the cyst is associated with a weaning cellular immune response (Nath & Sinai, 2001). The cysts have a predilection for certain sites in the host such as muscle, brain or retinal tissues. Ingesting tissues of an intermediate host containing tissue cysts infects carnivorous and omnivorous animals. This is also the route whereby cats (and other Felidae) become infected, thereby closing the life cycle of the parasite.

Congenital transmission is a unique method that this parasite has developed to maintain an infectious reservoir in certain intermediate hosts. During pregnancy the tachyzoites can transfer the placenta and infect the developing offspring. In some species this can occur during successive pregnancies (Owen & Trees, 1998; Webster, 2001; Marshall et al., 2004). In humans, congenital transmission is thought to be a one-time event, occurring when a pregnant woman becomes infected with the parasite for the first time in her life. For sheep and rodents, evidence has been reported indicating that this may occur during successive pregnancies. Although congenital transmission has been reported in pigs, it is not known whether transmission can occur during multiple pregnancies. In rodents, the congenitally infected offspring may transfer the disease to their offspring leading to a long-lasting reservoir of Toxoplasma gondii even in the absence of Felidae as definitive host (Webster, 1994). In immunocompetent humans a primary infection is followed by a lifelong immunity causing the parasite to remain in its encysted stage during lifetime, preventing transfer of infection to the fetus in women who have encountered the infection prior to pregnancy.

**Epidemiology**

Due to the ubiquitous presence of the parasite, infection in humans is quite common. In some populations up to 100% of the individuals have been shown to be seropositive for Toxoplasma (Tenter, 2000). Prevalence rates differ, depending amongst other things on the environmental conditions of oocyst survival. Prevalence of Toxoplasma is high in humid tropical areas and low in hot and dry areas. Prevalence in cold areas is also low. The prevalence of infection in a number of European countries (e.g. United Kingdom, Sweden and the Netherlands) shows a rapid decline over the past years (Walker et al., 1992; Nokes et al., 1993). A study performed in the Netherlands in 1987 showed that 50% of the population aged 30–34 years had experienced a previous Toxoplasma infection, whereas a study performed in 1996 showed that 37% of this age group was seropositive (Figure 1; L.M. Kortbeek, unpublished results). It is not clear why prevalence has dropped over the past years. It may be due to a change in consumption patterns, food handling and outdoor activities. On the other hand, the
decreased prevalence in the human population parallels a decrease in *Toxoplasma* infection rates observed in pigs (Figure 2). The change to intensive farm management practices whereby animals are confined within buildings may have contributed to a decrease in *Toxoplasma* seroprevalence. This in turn may have led to fewer consumers becoming infected.

Figure 1. *Toxoplasma* seroprevalence in the Dutch population by age groups in the years 1987 ($n = 28,000$) and 1996 ($n = 7521$).

Figure 2. *Toxoplasma* infection in Dutch slaughter pigs in the period 1969–2001.
Risk factors

Risk factors for both humans and livestock include the ingestion of fruit, vegetables, soil or water contaminated with sporulated oocysts shed into the environment by cats during a few weeks following infection (Tenter, 2000). It is assumed that the latter only occurs once in the lifetime of a cat. Prevalence studies in European cats have shown that approximately 50% of the cats have experienced a *Toxoplasma* infection, indicating that these pets are the cause of a serious environmental burden of parasites (Webster, 2001). Disposal of cat litter boxes via the toilet or into compost garbage collection systems may pose as yet unknown environmental problems. Infection of marine mammals along the west coast of the United States is thought to be due to the outlet into the Pacific Ocean of sewage systems containing cat box litter disposed via home toilets (Dubey *et al*., 2003b). Compost production systems may not reach temperatures high enough to kill sporulated oocysts. Compost, which is used by a few pig farms to improve iron uptake (I.A.J.M. Eijck, personal communication), may be involved in the transfer of Toxoplasmosis to pigs.

The main risk factor for humans to contract Toxoplasmosis is the consumption of raw or undercooked meat from animals that have been previously infected with the parasite (Cook *et al*., 2000). It is not known how many tissue cysts result in the infection of human beings, but ingestion of one cyst (containing hundreds of bradyzoites) is sufficient for a cat to become infected. Pigs, goats, sheep and poultry are the major meat sources of human infection (Tenter, 2000; Aspinall *et al*., 2002). One pig may be consumed by 200–400 different individuals so that there is a tremendous amplification of the risk to become infected (Fehlhaber, 2001). During the production of various meat products, meat of many animals is mixed, which also amplifies the risk in cases where only a few animals would be infected (Aspinall *et al*., 2002). Of interest is the fact that beef is not an important source of human infection (Dubey & Beattie, 1988). Although cattle can become infected with *Toxoplasma gondii*, this does not result in the appearance of infectious tissue cysts in their meat. Epidemiological studies in Europe have indicated that meat consumption could account for almost 60% of the *Toxoplasma* infections, whereas contact with soil (gardening) may be held responsible for approximately 20% of the cases (Cook *et al*., 2000). Kitchen hygiene with respect to the handling of meat may also be a risk factor for humans to contract Toxoplasmosis. Examples include the use of the same knife to cut raw meat and subsequently cut fresh salad or the tasting of raw minced meat during flavouring with salt and pepper (Kapperud *et al*., 1996; Tenter *et al*., 2000).

*Toxoplasma gondii* can also be transmitted via the milk of infected goats (Riemann *et al*., 1975; Tenter *et al*., 2000). It is not known whether goat cheese prepared from animals shedding the parasite is still infectious. Byproducts of goat cheese processing (whey) are sometimes fed to pigs, which may potentially lead to the transfer of *Toxoplasma* to these animals.

*Toxoplasma gondii* is effectively killed by heating at temperatures above 67 °C for a few minutes (Dubey, 2000). Overnight freezing at –12 °C also kills the majority of tissue cysts (Kotula *et al*., 1991), whereas the curing of meat with salt does not seem to
affect the parasite immediately (Dubey, 2000). Irradiation with low dosages of Cesium 137 can also be a suitable method to destroy the parasite (Dubey et al., 1998).

**Animal-friendly production systems**

Indoor housing of farm animals is not regarded as being in favour of animal welfare, and due to social pressure the bioindustry in Western Europe is urged to re-introduce outdoor housing. In the Netherlands different animal-friendly pig-production systems have therefore been introduced. On modern intensive farms following a high hygiene protocol, pigs are housed indoors mostly on concrete-slatted floors and are fed regular pelleted pig feed. So-called free-range pigs are allowed outdoor access, are given straw bedding and are also fed regular pelleted pig feed. Pigs from organic farms are kept according to regulations set up by the European Union (EU regulation nr 2092/91), which includes outdoor access, straw bedding and ‘organic’ pig feed. Organic pig feed often contains the same (plant) ingredients as regular pig feed, but is grown on farms that do not use inorganic fertilizers or pesticides. Since the BSE crisis, in the European Union it is not allowed to feed pigs with products of ‘animal’ origin. So pigs can be considered as vegetarians, although they are in fact omnivorous.

Whether animal-friendly production systems lead to a re-emergence of *Toxoplasma* infections is not yet known. This question was therefore the subject of research performed in the past few years by the Animal Sciences Group of Wageningen University and Research Centre. Results show that indoor housed pigs were free from *Toxoplasma* infection whereas almost 3% of the animals raised in animal-friendly production systems had previously been infected with *Toxoplasma* (Kijlstra et al., 2004). On 70% of the organic farms tested, sows were seropositive whereby per farm on average 15% of the sows showed evidence of a previous *Toxoplasma* infection (I.A.J.M. Eijck; personal communication). The source of infection is not exactly known yet, but may include ingestion of sporulated oocysts deposited in the environment via cats. Pigs are known to catch rats and mice and earlier research concerning risk factors for *Toxoplasma* infection on pig farms has already shown that poor rodent control is involved (Weigel et al., 1995). Our own field studies confirm these observations. All conventional pig farmers use chemical rodenticides, whereas up to 30% of the farmers on animal-friendly farms do not, but rather rely on the use of cats for rodent control on their premises. An analysis of risk factors and possible means of controlling *Toxoplasma* infection on organic pig farms based on HACCP methodology is presented in the Appendix.

Since cats have been recognized as an important risk factor (Dubey et al., 1995a), the effect was studied of *Toxoplasma* vaccination of farm cats on *Toxoplasma* seroprevalence in pigs. Some time after the introduction of the cat vaccine, the seroprevalence showed a small but statistically significant decrease in the seroprevalence of pigs where cats had been vaccinated (Mateus-Pinilla et al., 1999). The small change could point to other more important risk factors, such as transfer via the ingestion of rodents. As will be mentioned later, rodents can be an important reservoir of the parasite even when cats had been absent for a long period of time (Webster, 2001).
Chickens are also a potential source of *Toxoplasma* infection in humans (Tenter et al., 2000). Most chickens used for consumption are raised indoors and probably do not have access to a source of *Toxoplasma* infection during their short lifetime. Organic chickens raised for meat production are allowed outdoor access and are slaughtered at an older age. Due to their longer life and due to the fact that they have access to various *Toxoplasma* sources, organic chickens could potentially become infected with *Toxoplasma*. So far this has not been studied but recent data show that a large percentage of free-ranging chickens have been infected with the parasite (Dubey et al., 2003a). At present there are no epidemiological data supporting the hypothesis that ‘animal friendly’ farming will have an impact on the incidence of human Toxoplasmosis. But this is also because at present the market share of organic meat is only a few percent.

**Toxoplasma infection in rodents: prevalences and routes of transmission**

Many studies have focused on the prevalence of *Toxoplasma* infection in wildlife animals. In this section we shall confine ourselves to rodents that may play a role in the transmission of infection to farm animals like pigs and poultry.

From field studies conducted on pig farms in Illinois (USA) during 1992 and 1993 it was learned that 2.1% of the house mice (*Mus musculus*) were seropositive for *Toxoplasma* (Dubey et al., 1995b). Infectious parasites were recovered from heart or brain tissue in 0.5% of the mice investigated. Sera from Missouri and Kansas (USA) collected in the period December 1974 – December 1987 and analysed for the presence of antibodies to *Toxoplasma gondii* showed a low prevalence (3%) of antibodies in mice (*Mus musculus* and *Peromyscus* spp.) and rats (*Rattus norvegicus* and *Sigmodon hispidus*), while medium-sized herbivores, like squirrels (*Sciurus* spp.), rabbits (*Sylvilagus floridanus*) and muskrats (*Ondatra zibethicus*) had prevalences of about 18% (Smith & Frenkel, 1995). Webster (1994) studied the prevalence of *Toxoplasma gondii* within 6 UK farmstead wild rat populations (*Rattus norvegicus*) and reported a mean prevalence of 35%. No statistically significant age, sex or site differences were observed in prevalence between or within populations irrespective of habitat type or presence of cats.

The prevalence of *Toxoplasma gondii* in the Czech Republic was < 1% in insectivores (n = 578), 12% in carnivores (n = 112), 1% in rodents except muskrats (*Ondatra zibethicus*) (n = 5163), 24% in muskrats (n = 437), 5% in lagomorphs (n = 293), 0% in ruminants (n = 456) and 2% in wild boars (*Sus scrofa*) (n = 136) (Hejlice et al., 1997). Another study from the Czech Republic showed *Toxoplasma* infection in 47% of the muskrats from a site with water heavily polluted with municipal wastes and 9% in muskrats from 3 sites with water slightly polluted with wastes, stressing the role of waste water as a source of *Toxoplasma* infection (Nezval & Literak, 1994).

A study from Ontario (Canada) showed that 11% of the mice (*Mus musculus*), 5% of the deer mice (*Peromyscus*), 3% of the rats (*Rattus norvegicus*) and less than 2% of the sparrows (*Passer domesticus*) investigated were seropositive. All samples from short-tailed field mice (*Microtus pennsylvanicus*), squirrels (*Sciurus carolinensis*), chipmunks (*Tamias striatus*), meadow jumping mice (*Zapus hudsonius*) and starlings (*Sturnus*...
vulgaris) were seronegative (Tizard et al., 1978).

How wild rodent populations become infected with Toxoplasma gondii is not exactly known, but congenital transmission may perpetuate the infection over successive generations. Webster (2001) concluded that this mode of transmission is the predominant route for Rattus norvegicus. Marshall et al. (2004) presented evidence that 75% of the transmission in the house mouse (Mus musculus) also occurs via the congenital route (Owen & Trees, 1998). Also studies in sheep favour this mode of transmission (Duncanson et al., 2001).

Toxoplasma gondii has been shown to affect the behaviour of its intermediate host, the rat: its chance of being predated by cats is increased. Rats, which normally avoid areas with cat scent, become attracted to cat urine odour following infection with Toxoplasma gondii (Berdoy et al., 2000).

Conclusions

Toxoplasmosis is an important parasitic disease worldwide causing substantial health problems in humans as well as in farm animals. Currently no vaccine is available and anti-parasitic drugs are either not effective (ocular Toxoplasmosis) or are associated with serious adverse side-effects. This means that prevention is currently the best method to manage the disease. Since the majority of human infections are due to the consumption of meat, emphasis should be on control of the disease at farm level or on implementing measures to test animals before the meat reaches the consumer. Indoor housing of farm animals as practised in intensive animal husbandry has resulted in the abrogation of the Toxoplasma problem in the pig industry. However, animal-friendly livestock-production systems are associated with a potentially higher prevalence of Toxoplasma infections and extra attention is needed to control transfer of infection on these farms. The access of cats to the farm premises, the use of compost and goat whey, and rodent control have been identified as risk factors that should be addressed on these farms.

Feed

Pigs become infected with *Toxoplasma* because non-processed feed (by-products and individual ingredients, including hay and straw) are contaminated with cat faeces or dead rodents

If infected cats can drop faeces onto stored feed products or if infected rodents have access to these products (and can die there), this can lead to contamination of the feed products with both oocysts and (rodent tissue) cysts. Several animals can become infected if fed with these products.

Pigs become infected with *Toxoplasma* because they are fed (infected) goat-whey

Some pig farmers feed organic goat-whey to their pigs. If whey is obtained from *Toxoplasma*-infected goats, the whey can contain *Toxoplasma* tachyzoites. This may lead to infection of all animals on the farm.

Visit and animal caretaker

Pigs can become infected with *Toxoplasma* through visitors and animal caretakers via oocysts on their shoes or clothes

- No access of cats or rodents to farm storage sites of by-products or other feed ingredients
- Feed producers should guarantee a cat- and rodent-free storage system (including control system)
- Forbid feeding goat-whey
- The supply of piglets should come from *Toxoplasma*-free farms
- Prevent cannibalism by introducing distracting elements (playing material)
- The use of clean instruments and tools
- The use by visitors of clean shoes and clothes before entering the farm area

</table>

1 Chance estimates whether the described risk occurs on the farm. It is ranked from 1 to 3; with 1 = chance of occasion is low, it occurs rarely or is theoretical; 2 = chance of occasion is mediocre, it can occur or occurs several times a year; 3 = chance of occasion is high, it occurs frequently.

2 Severity gives an estimate of the number of animals possibly affected by *Toxoplasma* when the risk becomes manifest. It is also ranked from 1 to 3; with 1 = the occasion has an influence on a single pig to all pigs in the pen; 2 = the occasion has an influence on a part of all the pigs on-farm (pig unit); 3 = the occasion has influence on (almost) all the pigs on-farm.
