Abstract. Nowadays, wheat is the most important crop for organic farming system. However, the varieties bred and tested in the conditions of organic farming system are still missing. It gives rise to very low level of yield in the Czech Republic (less than 50% of level of convention one in the same conditions). One of the reasons is that the ideotype of organic breeded variety is different from conventional one. The varieties suitable for organic farming system differ in many respects from those adopted in conventional farming. The first difference is obvious from the conventional tests of use value of the varieties, taking just some direct indicators influencing the main parameter (yield) into account. Generally speaking, the features to be tested can be divided into 4 groups: the morphological, the biological, the economic and quality parameters. The conventional varieties are bred in conditions characterised by an abundance of soluble nutrients, and therefore, their root systems are not adapted to an insufficiency of nutrients or weaker bonding of nutrients. The competitiveness to weeds has also been ignored. Any conventional variety, which has never confronted any strong weeds during the breeding process, cannot be assumed to be competitive enough in the conditions of an organic agroecosystem. Resistance to diseases and pests can be similarly characterised. The variety is protected by pesticides throughout the conventional breeding process. Because of the seasonal fluctuations in weather, we need a plastic and flexible variety. They are also different from the point of view of their qualitative parameters.

Key words: organic farming, breed wheat, ideotype, variety

Introduction

Bread wheat is one of the most important food crops of the conventional and organic farming systems (FAO, 2006). The efficiency of cultivation and yield of bread wheat varies in different parts of the world. On the one hand, there are organic farmers achieving only half the yield of conventional farmers and on the other hand, some organic farms provide almost the same yield as the conventional ones (the organic yield is usually slightly lower) (Moudrý et al., 2007). There are many reasons for this and some organic farms in Austria and the Czech Republic may serve as an explanation. They exist in the same land-climatic condition and they may be only tens of kilometres from each other, but the Czech organic farmers achieve half the yield of their conventional counterparts. Austrians achieve 80-90% of the yield of the conventional farmers (Konvalina et al., 2007a). There are many reasons for this, perhaps the most important being that organic farming has a much longer tradition in Austria, where farmers use the principles and methods of organic agrotechnology much more effectively. A crucial factor is that the Austrian system of certification of organic varieties is better developed (Löschenerberger & Lafferty, 2005). Austrian farmers mostly grow conventional varieties, but they have extensive information
available on their reaction to low-input farming system. According to many authors, the choice of variety is a crucial factor in efficient organic farming.

Modern cultivars of wheat do not satisfy all the requirements and demands of organic agriculture. Therefore, more attention should be given to the breeding of specific cultivars adapted to the agronomic conditions on organic farms and complying with the philosophy of organic farming (Lammerts van Beuren, 2002). Nowadays, new breeding programmes are emerging because the conventional varieties of bread wheat have a very different genetic background (Kunz & Karutz, 1991). Lammerts van Bueren (2003) points out that, in order to avoid the use of chemical fertilizers and pesticides in organic agriculture, agroecological principles should be applied to enhance the self-regulatory capacity of the agroecosystems. Organic farmers require cultivars that can be multiplied and grown in the organic farming system with no undue negative effect on the health and function of the agroecosystem (Kunz & Karutz, 1991). Cultivars should therefore have the ability to perform under a low input of organic fertilizers, a good root system, the ability to interact with beneficial soil microorganisms and to suppress weeds, and the ability to produce a healthy crop and healthy propagules (Lammets van Bueren et al., 2002, 2003).

Materials and methods

This paper is partly the result of an extensive literature search. The facts published in this article are based on many other projects, seminars and workshops organised in cooperation with scientists, breeders and organic farmers between 2005 and 2007 (see Konvalina et al., 2007c for details). Old prevailing arguments about the ‘suitability’ of conventional varieties have been rebutted by the scientific community (see results of the European Project COST 860 for details) and by studies carried out by organic farmers (see http://www.cost860.dk for details). Many results are also based on a known working version of the ‘methodology’ for testing the suitability of varieties of bread wheat which was first defined, prepared and tested in field conditions and published as a complete methodology for use in organic and low-input farming systems in the climatic conditions of Central Europe by the authors of this article (for details, see Konvalina et al., 2007a).

Results and discussions

Can the ideotype of ‘the conventional variety’ be suitable for the organic farming system?

The varieties suitable for organic farming system differ in many respects from those adopted in conventional farming. The first difference is obvious from the conventional tests of use value of the varieties, taking just some direct indicators influencing the main parameter (yield) into account. Generally speaking, the features to be tested can be divided into 4 groups: the morphological, the biological, the economic and quality parameters (Konvalina & Moudrý, 2007b). Most of the morphological features are not usually tested in the conventional farming system; only the length of the plant is taken into consideration. However, other features have an effect on the degree of total yield in a low-input farming system. In respect of the biological features, all the important factors are tested and evaluated in varied conditions. Considerable stress is placed on the testing and evaluation of the economic features.
However, some important features for organic varieties are not taken into account. Density of spike may serve as an example; a less dense spike can increase the resistance to fungal diseases but affects the spike in an indirect way (the spike gets dry easily) and the total productivity can be improved by the length of the spike and higher TGW. Better assimilation of sunlight and better distribution of nutrients in the plant can also be positive effects. Concerning the quality parameters, maximum levels of quality are now achievable. The particularity of organic varieties (e.g. the different composition of storage proteins) is nevertheless not taken into consideration. The choice of variety determines the flavour, which should always be taken into account (Konvalina, 2007a). In 2001, the testing of varieties in the organic farming system was initiated in Austria, the only country in the European union where this has happened. According to the experience resulting from these tests and studies, many of the results of conventional tests cannot be taken into consideration (e.g. the efficient use of nitrogen, suppression of weeds, rapid mix test) (Konvalina, 2007a). A number of the varieties recommended in the conventional system are no longer grown in the organic farming system.

Concerning the critical points of conventional and certified bred varieties of wheat, there are 4 groups of problems (Wolfe, 2006) and they determine each other. They are: the efficiency of absorption and use of nutrients, competitiveness to weeds, resistance to diseases and pests, degree and stability of the yield and the qualitative parameters of production (See Table 1).

### Nutrient uptake and utilization efficiency

Organic farming is a system using a limited quantity of nutrients (especially nitrogen) and serial applications of nitrogen (Köpke, 2005). The possession or non-possession of the ability to absorb nitrogen in early spring is an important issue in the growing of winter varieties of cereals in an organic farming system; cold wet soil is characterized by a low degree of microbial activity. The mineralization of nutrients (especially of nitrogen) is limited in this period (Moudrý, 2003). The efficient absorption of nitrogen is also an important factor; it provides good-quality production and development of plants in the early stages of growth. (Steinberger, 2002). Varieties must be adapted to the lower inputs of nutrients into the agroecosystem (Lammerts van Bueren, 2002).

A wide range of studies have been carried out in the last few years; their common purpose has been to determine the changes in efficiency of varieties during the breeding process, and changes in the efficiency of the exploitation of nutrients. Muurinen et al. (2006) studied the efficiency of the exploitation of nitrogen in wheat, oat and barley, bred in Finland between 1909 and 2002. Modern varieties of wheat and oat were more they absorbed more nitrogen and were able to use it more efficiently than the older ones. It was different in the case of barley. They also point out that the improvement in the efficiency of absorption and use of nitrogen was caused by the more efficient use of the absorbed nutrients in a plant, not the increased ability of absorption of nutrients by the root system.

Ericson (2006) states that modern varieties provide a higher efficiency in absorption and use of nutrients than land races (various amounts of industrial fertilizers). This is valid for conventional farming systems. However, this statement is not so unambiguous for natural low-input farming systems. Gorny (2001) states in his
study that land races of baking wheat provide a higher efficiency in the absorption and use of nitrogen than modern European varieties in low-input farming systems. He clarifies the reason for this in his study. Slafer et al. (1990) studied 6 varieties of baking wheat which had been bred between 1912 and 1980 and found out that the ability of the root system to absorb nitrogen did not improve during the growing and flowering season of the breeding process. The breeding caused an increase in the grain yield thanks to a change of the harvest index, the harvest index of nitrogen and the increasing number of grains. The change in the harvest index was greater than the change in the harvest index of nitrogen; it led to a ‘dilution’ of nitrogen and a lower concentration of nitrogen in the grain. Because of that, the varieties being bred in conditions of an abundance of soluble nutrients (especially nitrogen) are not able to absorb nutrients from less accessible bonds, use the accessible nutrients more efficiently, and thus need less accessible nutrients. This fact supports the carrying out of the breeding process in the conditions of the organic farming system, and the selection of tribes with greater potential.

Baresel et al. (2005) also support this idea in their work. They were studying the varieties of wheat and found the conditions of organic farming very varied and dissimilar to the conditions of conventional farming. The varieties adapted to the conditions of conventional farms may not have been adapted to the conditions of low-input farming. The efficient genotypes (those able to absorb and use nitrogen in the first stages of their growth) are more suitable for the organic farming system. Most modern varieties are well used and applied in farming systems which are characterized by high inputs of nutrients. They provide a low degree of interaction between-genotype and the environment. They do not achieve the required baking quality in low-input conditions. On the other hand, old cultivars and biological varieties contain more protein in grains (in both organic farming and conventional systems). The higher proportion of protein is usually connected with a lower level of yield (Ericson, 2006).

A well-developed root system, responsive to the interaction with the soil edaphone in a positive way, is a very important aspect of the efficient absorption of nutrients (Lammerts van Bueren, 2002). The growth of roots is more important than the growth of upper phytomass in a soil characterized by a lower concentration of accessible nitrogen. On the other hand, the shape of the root system is influenced not only by the soil structure, but by the proportion of nutrients and water in the soil, by a genetic factor (Fitter, 1991, Fitter & Stickland, 1991) and by the selection of varieties which provide a high level of yield in the conditions of conventional farming, but with negative consequences (Siddique et al., 1990). This means that the selection of suitable varieties for low-input farming system should be applied in the conditions of organic farming (Lammerts van Bueren, 2002).

The selection of an efficient root system, adapted to the absorption of nutrients from the soil, should take into account the limited competitiveness of varieties for the assimilates and a good position of the roots. A long and deep root system with a lot of small young roots forms a better and richer branching with more capillary roots. The deep roots assure a sufficient absorption of water and nutrients from the deeper layers of the soil profile (Köpke, 2005).

The interaction between the root system and the other soil organisms (bacteria, fungi) is a very important aspect of the agroecosystem; it increases the extent of mineralization of nutrients (Lee & Pankhurst, 1992; Mäder et al., 2000). Hetrick et al.
(1993) realised that modern varieties of wheat responded less to mycorrhizal symbiosis. The interaction between microorganisms and roots is determined by genetic factors; nowadays, this factor is not taken into consideration in the breeding process.

**Weed suppression**

Weed plants are one of the main factors limiting the level of agricultural yield. Because of the availability of herbicides in the last 50 years, the competitiveness of field crops to weeds has been overlooked. The relationship between the cultured and the weed plant was supposed to be negative. However this relationship could contribute to the formation of a stable agroecosystem (Lammerts van Bueren, 2002) as the weeds can play a positive role in the agroecosystem (Wolfe, 2002). We cannot consider the cultured plant as naturally competitive to weed plants, because it has not confronted any important competitive weed plant during the breeding process. Modern conventional varieties are not selected in accordance with their indirect morphological or biological features; however, these features - the shape of a tuft, the length of a plant or the position of leaves - contribute to a increase in competitiveness. Nevertheless, the competitiveness of the currently bred conventional varieties can be tested in the conditions of an organic farming system. Sufficient tillering is one of the complex of characteristics responsible for high competitiveness against weeds (Kruepl et al., 2006). Selection is also one of the main parameters in this respect (Köpke, 2005). The architecture of a plant has an important effect also (length of stalk, percentage of leaves, position, compactness and shape of leaves) (Regnier & Ranke, 1990). Medium to tall varieties are the most suitable in this respect (Moudrý, 2003). Kunz & Karutz (1991); Eisele & Köpke (1997); Müller (1998) and Köpke (2005) also point to the higher competitiveness of the taller varieties. However, the taller varieties also cause such problems as lodging (Kruepl et al., 2006). Fast growth of the plant in the first stages of life is a very important aspect as it allows an early achievement of a high LAI value. A planophile position of leaves (>45º) in the first stages of growth assures a higher degree of coverage of the soil surface, and a deterioration in the growing conditions for weeds, although in the worse nutritive stations this can also lead to the slower development of the plants. An erectophile position of leaves is a more favourable feature for the later stages of the plant's growth (Hoad et al., 2005). The competitiveness of plants also depends on the speed of columnning, LAI, capacity of the upper phytomass and the tallness of plants in the DC 31-75 stage (Köpke, 2005).

A number of authors also point out that competitiveness is determined by a good ability to absorb nutrients in low-input farming conditions. Varieties must be adapted to the negligible use of nitrogenous fertilizers and be able to cover the soil as fast as possible (Kunz & Karutz, 1991; Eisele & Köpke, 1997; Müller, 1998). Aleopatic secretions may also influence the growth of other crops. However, according to studies, aleopatic secretions play an important role in the growing system of rye and oat, but not wheat (Köpke, 2005). Nevertheless, research results also rebut this fact; they point out that the aleopatic potential may lead to a reduction in yield and quality (Regnier & Ranke, 1990).

**Disease resistance**
A plant's health depends primarily on preventive measures, which can mean the creation of optimum conditions for growth, prevention against stressors, and the taking into account of the natural toleration to plant competitors. Several diseases occur not because of poor growing conditions, but because of an imbalance between the plant and the environmental conditions; this can lead to an imbalance in the metabolism processes, and the attraction of insects, fungal and bacterial diseases (Tamis & Van den Brink, 1999).

The main selection criterion for good breeding is not the level of resistance; it is rather the ability of a specific plant to create a certain level of yield and quality in spite of the pressure of infectious diseases (Lammerts van Bueren, 2002). The resistant plant should not be just resistant, but its morphological features should also guarantee its resistance in conditions of higher infection. This fact is not taken into consideration in the selection process of conventional varieties. However, it is one of the reasons for the reduced resistance of conventional varieties, which are without any chemical protection against fungal diseases, as the following examples show: the occurrence of *Septoria nodorum* is influenced by a plant's architecture (Kunz, 1983), in that the transfer of spores from leaves to spikes by raindrops may be reduced by a longer distance between spike and flat leaf (Köpke, 2005); high plants are more resistant (Kunz, 1983) and *Fusarium* spp, an infection of spikes, is influenced by the distance between spike and flat leaf (Engelke, 1992).

**Yield stability and product quality**

Organic yield is in case of the best organic farms about 20-30 % lower than the conventional (Moudrý, 1997; Mäder et al., 2002; Lammerts van Bueren et al., 2002). The quality and stability of the yield are the main priorities for organic farming which does not lay stress on the quantity of production. Farmers usually need to grow ‘reliable’ and ‘solid’ varieties which are able to tolerate potential fluctuations in the weather and the potential pressure of diseases; they must in any case be able to provide sufficient yield of grains and straw. The target variety should be bred to provide a lower, but stable yield. The selection of the conventional varieties is based on the yield level and it is carried out in uniform conditions. According to the results of tests carried out by organic farmers, conventional varieties which provide a high yield are not as efficient as organic varieties in marginal areas. The suitability of the conventional varieties may be tested in the conditions of the organic farming system where relatively stable varieties providing a high yield can be selected.

A variety may be characterized by specific features due to the interaction between genotype and environment; a favourable factor may be that such varieties can be marketed as a regional product. This aspect is based on the fact that its flavour adds special features and character to the variety (Lammerts van Bueren & Hulscher et al., 1999).

The high baking quality of the organic varieties is characterized by the proportion and total content of crude protein, high value of the Zeleny - sedimentation value, flour binding capacity and flour yield, Falling number and test weight. The baking quality of wheat is a complex feature; the breeding of such varieties (to a high quality) is a long and difficult process (Fossati et al., 2005).

Organic methods of farming may have negative effects on the technological value, especially in the case of the crucial crude protein content (Moudrý & Prugar,
2002). The proportion of crude protein in grain is reduced because of the reduced availability of soluble nitrogen (Krejčířová et al., 2006). The composition of storage proteins also changes, there are more protoplastic proteins (albumins and globulins) (Krejčířová et al., 2007), and this increases the nutritive value of grain.

Table 1: Criteria for organic plant breeding and propagation strategies derived from the non-chemical and agro-ecological approach) (according to Lammerts van Bueren, 2002)

<table>

**Conclusions**

The importance of organic farming has been increasing worldwide. However, the selection and breeding of suitable varieties for the organic farming system have been disregarded. According to most viewpoints, the ideotypes of an organic and conventional variety are very different. The rentabile conventional varieties cannot be assumed to be as rentabile in the organic farming system also. There are several reasons for this statement. The conventional varieties are bred in conditions characterised by an abundance of soluble nutrients, and therefore, their root systems are not adapted to an insufficiency of nutrients or weaker bonding of nutrients. The competitiveness to weeds has also been ignored. Any conventional variety, which has never confronted any strong weeds during the breeding process, cannot be assumed to be competitive enough in the conditions of an organic agroecosystem. Resistance to diseases and pests can be similarly characterised. The variety is protected by pesticides throughout the conventional breeding process. Thanks to the harmony of the production process, the pressure of diseases and pests is usually lower in the organic farming system. On the other hand, a variety unable to provide the required level of yield without pesticides is vulnerable. Because of the seasonal fluctuations in weather, we need a flexible variety. Can the conventional variety, having been bred in conditions of an abundance of nutrients and instruments of plant protection, be stable and flexible enough? Yes, it can. But it must be a variety which is bred and grown in
particular regional land-climatic conditions. However, the varieties imported from distant areas are characterised by different features. They are also different from the point of view of their qualitative parameters. Concerning the qualitative parameters of production, the conventional varieties grown in organic farming conditions are characterised by a low proportion of nitrogenous elements in grain (less than 10 %). It could be better to breed directly for a lower yield level in a variety (about 10-20 %) which could then achieve better qualitative parameters.

Organic farming cannot avoid modern conventional varieties. The system certifying conventional varieties for the organic farming system therefore plays an important role (see the Austrian example). Breeding of organic varieties remains an important task for the future. On the other hand, the selection of suitable tribes with regard to the qualities necessary for an organic variety could be a good solution at the beginning of the breeding process. The formation of clear organic breeding processes would be the next important step; it would close the cycle of the development of organic farming which began with conventional seeds which were then reproduced in the organic farming system. A certification system of the conventional varieties for organic farming system has already been introduced; specialised regional breeding stations will be established in the future and the breeding process will be transmitted directly to the organic farms (participatory breeding). Stable and flexible varieties will be created which will be adapted to regional conditions and which will be able to provide an abundance of food in weaker years (characterised by strong fluctuations in weather).
