ABSTRACT
Increasing subsoil organic carbon (C) inputs could potentially mitigate climate change by sequestering atmospheric CO2. Yet, microbial turnover and stabilization of labile C in subsoils are regulated by complex mechanisms including the availability of nitrogen (N), phosphorous (P), and sulfur (S). The present study mimicked labile organic C input using a versatile substrate (glucose) to address the interaction between C-induced mineralization, N-P-S availability, and microbial physiology in topsoil (20 cm) and subsoil (60, 100, and 300 cm) from a temperate agricultural sandy loam soil. A factorial incubation study (42 days) showed that net losses of added C in topsoil were constant, whereas C losses in subsoils varied according to nutrient treatments. Glucose added to subsoil in combination with N was fully depleted, whereas glucose added alone or in combination with P and S was only partly depleted, and remarkably 59–92% of the added glucose was recovered after the incubation. This showed that N limitation largely controlled C turnover in the subsoil, which was also reflected by microbial processes where addition of glucose and N increased β-glucosidase activity, which was positively correlated to the maximum CO2 production rate during incubation. The importance of N limitation was substantiated by subsoil profiles of C source utilization, where microbial metabolic diversity was mainly related to the absence or presence of added N. Overall, the results documented that labile C turnover and microbial functions in a temperate agricultural subsoil was controlled to a large extent by N availability. Effects of glucose-induced microbial activity on subsoil physical properties remained ambiguous due to apparent chemical effects of N (nitrate) on clay dispersibility.

1. Introduction

Globally, subsoils (> 0.2 m) contain more than two thirds of the soil organic carbon (SOC) within the upper 3 m soil profile (Jobbagy and Jackson, 2000). Thus, despite of low SOC concentrations in mineral subsoils, their extensive volume holds the potential for substantial carbon (C) sequestration (Jobbagy and Jackson, 2000; Rumpel, 2014). This is supported by generally slow rates of C turnover in subsoils as evidenced by high mean 14C-SOC ages (Rumpel and Kögel-Knabner, 2011). The delineation of subsoils is not strictly defined, but in agroecosystems it is usually considered as the soil below the plough layer or A horizon.

Management of agroecosystems to enhance subsoil organic C storage could potentially be a strategy to mitigate climate change by reducing the increase in atmospheric CO2 concentration (Lorenz and Lal, 2005; Kell, 2011; Lynch and Wojciechowski, 2015). Principally, organic C sequestration in subsoils is controlled by the balance between organic matter inputs and losses. Inputs occur predominantly in the form of plant litter, rhizodeposition (including root exudates), and dissolved organic C, whereas losses mainly result from microbial respiration, which is linked to microbial population dynamics and activity (Fernandes et al., 1997; Hedges et al., 2000; Michelzik et al., 2003; Wilhelm et al., 2004). Hence, organic C inputs, e.g., by deep rooted crops, are required for increasing the subsoil C content, but the eventual long-term C sequestration depends on the interaction between C input and microbial activity, also involving physico-chemical mechanisms of C stabilization (Salomé et al., 2010; von Lutzow et al., 2006). It is generally acknowledged that three major mechanisms control the persistence of organic C in soils, i.e., (i) selective preservation through chemical recalcitrance of organic substrates, (ii) physico-chemical stabilization through interaction between organic C and soil minerals, and (iii) spatial separation of organic C from decomposition by microbes and extracellular enzymes (Kroll et al., 2003; Lorenz and Lal, 2005; Schmidt et al., 2011). In nutrient poor subsoils, microbial mineralization of deposited organic C could also be limited by stoichiometric constraints in the availability of nitrogen (N), phosphorous (P) and/or...
sulfur (S) as related to the requirements in microbial biomass, where C:N:P:S typically occur at a ratio of around 100:15:2:1 (Xu et al., 2013, 2015). As shown in studies of Australian soils, sequestration of stable organic C in subsoils may eventually depend on products of microbial anabolism, which are enhanced by balanced stoichiometry of C:N:P:S according to microbial biomass requirements (Orgill et al., 2017). Yet, a recent study of acidic tropical forest and plantation soil concluded that the role of subsoil as a long-term sink of SOC could be questioned under conditions of increased N and P availability due to alleviation of microbial nutrient limitation (Meyer et al., 2018). Such apparently divergent results may be reconciled through the interaction of mechanisms related to microbial physiology, C turnover and C stabilization, but so far these interactions are poorly studied in subsoils. In particular, microbial dynamics related to subsoil C sequestration may depend on abiotic and biotic soil properties, including nutrient availability, which need to be better understood.

In the present laboratory study, we mimicked labile organic C input to a temperate agricultural sandy loam soil down to 300 cm depth using a simple, versatile substrate (glucose), which can be mineralized by the majority of heterotrophic microorganisms (Baldock and Oades, 1989; Hill et al., 2008). We tested the role of N, P and S availability on C mineralization, microbial physiology, and soil structural stability (clay dispersibility). The aim was to pursue whether different nutrient availability would link to an effect on microbial metabolism and soil properties, which could lead to divergent subsoil development and resultant conditions for C sequestration.

2. Materials and methods

2.1. Soil sampling and characterization

Soil was sampled in December 2015 from an excavated soil profile (0–300 cm) under an unfertilized temperate grass field at Foulumgaard Experimental Station, Aarhus University, Denmark (56°29′N, 9°34′E). The soil was a sandy loam, classified as Typic Hapludult, with an upper black Ap horizon (0–40 cm) overlaying a slightly weathered Bw1 horizon (40–70 cm) and a Bw2 horizon showing signs of clay accumulation (70–100 cm). The lower part of the soil profile was a rather uniform clayey C horizon (100–300 cm). The B and C horizons were light brown without visual signs of redox interphases related to anoxic conditions (such as pseudogleys). Fragments of roots were seen in the Ap and Bw1 horizons. Soils were sampled at 20, 60, 100 and 300 cm depth from three sides of the excavated profile walls and pooled to cover small-scale heterogeneity. The soils were air dried, sieved (< 2 mm), and stored at 2 °C until use. Chemical, physical and biological properties of the soil horizons are shown in Table 1.

2.2. Carbon turnover at different C:N:P:S stoichiometry

Carbon turnover to CO2 was measured in an automated set-up with 50-g soil samples (dry wt basis) incubated at 40% water holding capacity (WHC) by adding appropriate volumes of water or nutrient solutions. Seven treatments were prepared with different ratios of added C, N, P, and S from autoclaved solutions of glucose (2.5 mg glucose C g−1 soil), KNO3, KH2PO4, and K2SO4 in demineralized (dem) water. The seven treatments represented amendments with (i) dem water as reference (Ref), (ii) glucose (Glu), (iii) glucose plus P and S at a C:P:S ratio of 100:1:1 (Glu + PS), (iv) glucose plus N at a C:N ratio of 10 (Glu + CN10), and glucose plus N, P and S at three different C:N:P:S ratios of (v) 100:10:1:1 (Glu + PS + CN10), (vi) 100:5:1:1 (Glu + PS + CN20), and (vii) 100:1.67:1:1 (Glu + PS + CN60). Nutrient solutions were mixed in appropriate stoichiometry for each treatment, pH was adjusted to native soil pH (Table 1), and after autoclaving (121 °C, 30 min) the solutions were added dropwise to soil conditioned in 100-cm3 steel rings. Three treatment replicates were prepared for each soil horizon (i.e., 84 soil
incubations in total).

For automated CO2 measurement, the soil samples were randomized and transferred to respirometer jars (0.5 L) that were incubated in a water bath at 20 °C in a RESPICOND VI respirometer (A. Nordgren Innovations AB, Bygdeå, Sweden). Each respirometer jar was equipped with a container holding 20 mL of 0.6 M KOH for trapping CO2 evolved from the soil. Decrease in the conductance of the KOH solution (reflecting CO2 uptake) was read hourly with platinum electrodes (Nordgren, 1988) during an incubation period of 42 days. The KOH solution was renewed when it was 50–60% saturated with CO2. The net C loss from soil samples was calculated as the difference between CO2-C trapped in jars with and without soil. Soil moisture contents were not adjusted, but remained at 35–38% WHC during incubation. For each nutrient treatment and soil horizon, cumulative C losses induced by added glucose with or without nutrients were corrected for basal soil respiration, but included potential priming effects (Kuzyakov, 2010).

After the incubation period, each soil sample (n = 84) was homogenized for analyses of remaining labile (residual) glucose content, enzyme activity, microbial metabolic diversity, and clay dispersibility. These assays were done within 2 weeks of soil storage at 2 °C except for remaining labile glucose that was measured after 5 weeks.

2.3. Remaining labile glucose

Remaining labile glucose was extracted from 2 g soil in 10 mL dem water by horizontal shaking (10 min, 150 rev min–1) followed by centrifugation (10 min, 4000g) and filtration (0.45 μm). Aliquots of 1 mL supernatant (or diluted supernatant) were transferred to 10-mL test tubes for immediate enzymatic quantification of glucose by reaction with 2 mL of an assay reagent with glucose oxidase, peroxidase, and o-dianisidine dihydrochloride (GAGO-20; Sigma). After incubation for 30 min at 37 °C (water bath), the reaction was stopped by adding 2 mL of 6 M H2SO4 and mixing thoroughly. Absorbance was measured at 540 nm (Spectronic Helios Alpha, Thermo Scientific) for quantification of oxidized o-dianisidine by reference to a standard curve prepared from glucose concentrations of 0–16 μg mL–1. Extractions and assays were carried out in duplicate for each soil sample and remaining labile glucose contents were calculated after subtraction of (minor) colorimetric background of reference soils for each soil horizon.

2.4. Enzyme activity and microbial metabolic diversity

Enzymatic β-glucosidase activity was determined as an indicator of microbial parameters involved in C cycling in response to nutrient addition (Chen et al., 2017). The assay was done with 1-g soil samples amended with 4 mL modified universal buffer (MUB, pH 6) and 1 mL p-nitrophenyl-β-D-glucoside (25 mM) according to Eivazi and Tabatabai (1988). Samples were incubated horizontally at 150 rev min–1 for 2 h at 20 °C. The reaction was stopped by adding 4 mL TRIS buffer (pH 12) and 1 mL CaCl2, followed by centrifugation (10 min, 4000g). Absorbance of the supernatant was measured spectrophotometrically at 400 nm for quantification of released p-nitrophenol (NP). Three 1-g samples were used per soil analysis; two for assays as described above and one for determination of colorimetric background.

Microbial metabolic diversity was determined as community level profiles of C source utilization (CSU) assayed by MicroResp (Campbell et al., 2003). This was done using 96-well microplates ( Fisher Scientific) with 0.4 g topsoil or 0.5 g subsoil (60, 100, and 300 cm) in each 1.2-mL deep-well. Nine C substrates (and dem water as reference) were included in the assay: α-glucose, α-galactose, N-acetyl glucosamine, α-glutamine, γ-aminobutyric acid, α-ketoglutaric acid, γ-malic acid, 4-hydroxybenzoate, and lignin (all from Sigma Aldrich, except 4-hydroxybenzoate from VWR). The C substrates were selected to represent carbohydrate chemicals, amino sugars, amino acids, carboxylic acids, and recalcitrant organic compounds of relevance for soil ecosystems (Brackin et al., 2013; R.E. Creamer et al., 2016). The substrates were added in 25-μL aliquots from stock solutions prepared to deliver 30 mg substrate g–1 soil water except for the less soluble 4-hydroxybenzoate and lignin that were prepared to deliver 7.5 mg substrate g–1 soil water (Campbell et al., 2003). Final WHC in the soil samples was around 55%. Each soil well was connected to a detection plate well containing solidified agar with NaHCO3 and a pH dye with dynamic color change by equilibrium with CO2 (Campbell et al., 2003). The absorbance of the detector plate wells was measured (570 nm) in a microplate reader before and after 5 h of incubation (SPECTROstar Nano, BMG LABTECH). Readings of detector plates were converted to headspace CO2 concentrations by reference to a calibration curve prepared from detector plate wells equilibrated with specified CO2 concentrations as verified by gas chromatography using an Agilent 7890 GC system (Agilent, Nærum, Denmark) configured as previously described (Petersen et al., 2012). Four replicate MicroResp assays were performed for each soil sample; subsequent statistical analyses were based on the means of these four assays.

2.5. Clay dispersibility

Clay dispersibility was analysed by gently transferring 10-g soil samples (dry wt basis) and 80 mL of artificial rainwater (12 μM CaCl2, 15 μM MgCl2, and 121 μM NaCl; pH 7.82, EC 2.24 mS m–1) to 125 mL plastic bottles. The bottles were rotated end-over-end for 2 min (33 rev min–1, 23-cm diameter rotation). After rotation, the bottles were left for sedimentation for 230 min, after which the top 60 mL of the suspension was gently transferred to 100-mL glass beakers using a pipette. Under magnetic stirring, two individual 10-mL subsamples of this suspension were transferred to pre-weighted glass vials for weighing the mass of dispersed clay after oven-drying at 110 °C for 48 h.

A control experiment was performed to test for potential chemical effects of nutrient solutions on clay dispersibility. This was done with subsoil (100 cm) subjected to the treatments Ref, Glu + PS, Glu + CN10, and Glu + PS + CN10. Soil was conditioned in 100-cm3 subsoil (100 cm) subjected to the treatments Ref, Glu + PS, Glu + CN10, and Glu + PS + CN10. Soil was conditioned in 100-cm3
3. Results

3.1. Rates and dynamics of CO2 production

Carbon dioxide production rates from SOC mineralization in topsoil reference treatments were consistently low during the incubation period, with a mean basal respiration rate of 0.15 μg C g⁻¹ soil h⁻¹ (Fig. 1). In subsoils, reference mineralization rates were likewise consistently low with means of 0.06 μg C g⁻¹ soil h⁻¹ for the deepest soil horizon (Fig. 1).

Adding glucose with different nutrient supplements resulted in divergent mineralization dynamics in topsoil and subsoils. In topsoil, all glucose treatments caused immediate stimulation of CO₂ production (i.e., within hours) and maximum respiration rates were recorded after 1–2 days of incubation. Highest stimulation was caused by Glu + PS + CN10 and Glu + PS + CN20 (maximum rates of 46.9 and 40.2 μg C g⁻¹ soil h⁻¹, respectively), whereas lowest stimulation was caused by Glu and Glu + PS (8.3 and 8.6 μg C g⁻¹ soil h⁻¹, respectively). In subsoils, glucose also stimulated CO₂ production, but only after longer lag-phases (4–13 days) and only in treatments with concurrent N amendment. This indicated that glucose was not mineralized in subsoil treatments with Glu and Glu + PS, whereas the highest rates were obtained by Glu + PS + CN10 and Glu + PS + CN20 (12.2–24.3 μg C g⁻¹ soil h⁻¹). After the peaks of glucose turnover rates, CO₂ production in all nutrient treatments and soil horizons decreased to background levels within 1–2 weeks.

3.2. Cumulative carbon losses and retention

In topsoil, the cumulative CO₂ losses corresponded to 71–77% of the added glucose C without significant difference among the nutrient treatments (Fig. 2a). In subsoils, the corresponding CO₂ losses were 30–57% in the presence of added N (Fig. 2a), but only 1–17% in the absence of added N (i.e., Glu and Glu + PS). Further, in the absence of added N, the cumulative CO₂ losses decreased with soil depth in accordance with the decrease in native soil TN concentrations (Table 1). Addition of PS together with N (Glu + PS + CN10) contributed to moderate increase (~1.2 fold) in cumulative C losses (cf. Glu + CN10).

Remaining labile glucose contents, as measured in the soil after 42 days, aligned with the pattern of cumulative C losses, i.e., with no...
residual glucose in topsoil and in subsoil treatments with added N (Fig. 2b). However, in subsoil treatments without added N, 59–92% of the nominally added glucose was chemically recovered after the incubation period (Fig. 2b).

Tentative mass balances of added C minus trapped CO2 and recovered glucose C indicated that the net C retained in topsoil was 23–29% of the added (Table 2), likely stabilized through microbial anabolism. The size of this net stabilized C pool was more variable in subsoils (Table 2) with a mean of 37% in treatments with added N and 15% in treatments without added N. Yet, among the treatments with added N, the relatively nutrient-poorer Glu + CN10 and Glu + PS + CN60 treatments resulted in higher estimates of net retained C as compared to the more nutrient balanced treatments Glu + PS + CN10 and Glu + PS + CN20 (Table 2).

### 3.3. Enzyme activity

The β-glucosidase activity in reference treatments after the 42 day incubation period (Fig. S1) was > 20-fold higher in topsoil (17.4 μg N Pg⁻¹ h⁻¹) than in subsoil (< 0.7 μg NP g⁻¹ h⁻¹), which aligned with enzyme activities in the native soil profile (Table 1). As compared to reference treatments, the β-glucosidase activity in topsoil with glucose and nutrient amendments was increased by 15–38% (Fig. S1). In subsoils, glucose without N amendment failed to stimulate β-glucosidase activity, whereas treatments with N amendment showed a pronounced increase in enzyme activity (Fig. S1), with highest stimulation for Glu + PS + CN10 treatment. Correlation analyses (Fig. 3) showed that the resulting β-glucosidase activity in subsoils after the 42 day incubation period was strongly correlated (r = 0.91; P < 0.01) to the maximum CO2 production rate during incubation. Such strong correlation was absent in topsoil (r = 0.38; P = 0.09).

### 3.4. Microbial metabolic diversity

In general, all nine C substrates in MicroResp were utilized by the microbial communities in topsoil treatments (i.e., S = 8–9), whereas varying substrate utilization was found in subsoil depending on the

**Fig. 2.** (a) Cumulative CO2-C loss and (b) remaining labile (residual) glucose content in topsoil (20 cm) and subsoils (60, 100, and 300 cm) after incubation for 42 days with glucose and nutrients at different C:N:P:S stoichiometry. Data are mean and standard error (n = 3) with letters indicating significant differences (P < 0.05) between treatments within the same soil depth. Treatments: Glu, glucose; Glu + PS, glucose plus P and S at a C:P:S ratio of 100:1:1; Glu + CN10, glucose plus N at a C:N ratio of 10; Glu + PS + CN10, Glu + PS + CN20, and Glu + PS + CN60, glucose plus N, P and S at C:N:P:S ratios of 100:10:1:1, 100:5:1:1, and 100:1.67:1:1, respectively.

**Fig. 3.** Correlation between maximum CO2 production rate during incubation and β-glucosidase activity after incubation for 42 days in topsoil (20 cm; white symbols) and subsoils (60, 100 and 300 cm; black symbols) treated with glucose and nutrients at different C:N:P:S stoichiometry. The correlation was significant for subsoils (line and correlation shown), but not for topsoil (r = 0.38, P = 0.09).
precedent nutrient treatments (Fig. 4a). Substrate richness in subsoils was highest ($S = 3–7$) in treatments combining N, P and S, whereas it was zero in reference treatments, and low in treatments without added N ($S = 0–2$). Further, none of the subsoil treatments showed positive mineralization response to lignin. The pattern of functional diversity ($H$) aligned with the pattern of substrate richness (Fig. 4b), substantiating a high metabolic diversity in topsoil and weaker diversity in subsoils, though relatively high in treatments combining N, P and S. Overall, the subsoil substrate richness and functional diversity were highest in the two nutrient balanced treatments Glu + PS + CN10 and Glu + PS + CN20.

The pattern of CSU in topsoil and subsoil was differentiated by PCA with a primary component (PC 1) explaining 87% of the variation (Fig. S2). Separation of nutrient treatments in individual soil horizons was
Fig. 5. Score plots of principal component analysis of carbon source utilization in (a) topsoil (20 cm) and subsoil from (b) 60 cm, (c) 100 cm, and (d) 300 cm. Utilization of carbon sources was assayed with soil from treatments incubated 42 days with glucose and nutrients at different C:N:P:S stoichiometry. Data are shown for individual replicates (n = 3) of each treatment. Numbers in parentheses represent the variation explained by the two principal components PC 1 and PC 2. Treatments: Ref, reference; Glu, glucose; Glu + PS, glucose plus P and S at a C:P:S ratio of 100:1:1; Glu + CN10, glucose plus N at a C:N ratio of 10:1; Glu + PS + CN10, Glu + PS + CN20, and Glu + PS + CN60, glucose plus N, P and S at C:N:P:S ratios of 100:10:1:1, 100:5:1:1, and 100:1:67:1:1, respectively.

Fig. 6. Clay dispersibility in topsoil (20 cm) and subsoils (60, 100, and 300 cm) after incubation for 42 days with glucose and nutrients at different C:N:P:S stoichiometry. Data are mean and standard error (n = 3) with letters indicating significant differences (P < 0.05) between treatments within the same soil depth. Treatments: Ref, reference; Glu, glucose; Glu + PS, glucose plus P and S at a C:P:S ratio of 100:1:1; Glu + CN10, glucose plus N at a C:N ratio of 10:1; Glu + PS + CN10, Glu + PS + CN20, and Glu + PS + CN60, glucose plus N, P and S at C:N:P:S ratios of 100:10:1:1, 100:5:1:1, and 100:1:67:1:1, respectively.

mainly related to the absence or presence of added N (Fig. 5). Further, in topsoil the Glu + CN10 treatment was separated from the three treatments combining N, P and S (Fig. 5a); yet, with increasing soil depth, this separation became increasingly weaker (Fig. 5b–d), suggesting an increasing role of N limitation with greater soil depth. It was found that the discriminatory (PC1) effect of all CSU substrates were similar (loading plots; Fig. S3) and thus not specifically related to presence of intramolecular N (present in three of the nine substrates); this was likely related to the short MicroResp assay time not facilitating microbial adaptation or growth responses.

3.5. Clay dispersibility

In topsoil reference treatments, the clay dispersibility was 6.4 mg g⁻¹, and no changes were imposed by the nutrient treatments after 42 days of incubation (Fig. 6). In subsoil reference treatments, the clay dispersibility was 46–53 mg g⁻¹, and effects of nutrient treatments were moderate and often non-significant. However, the Glu + CN10 treatment was a notable exception. Here, subsoil clay dispersibility was much lower than in the other treatments, i.e., as low as 3–4 mg g⁻¹ for subsoil from 100 to 300 cm (Fig. 6). Yet, interpretation of this result in terms of microbial effects was challenged by control experiments showing that treatments with Glu + CN10 and Glu + PS + CN10 also reduced clay dispersibility, even after a soil incubation time of only 5 h (Fig. S4). This suggested an immediate chemical effect of the Glu + CN10 and Glu + PS + CN10 treatments on clay dispersibility, whereas such a chemical effect was not mediated by the Glu + PS treatment (Fig. S4).

4. Discussion

4.1. Nutrient limitation in subsoils

The fastest mineralization of glucose in topsoil was observed in treatments combining N, P and S. Yet, the overall C losses after 42 days were similar among treatments with and without added nutrients, signifying sufficient native nutrient availability in the topsoil for full microbial glucose mineralization over time. This agree with results from previous studies where addition of C with nutrients (N or P) to forest, fallow, or plantation soil significantly increased the maximum CO₂ production rate without affecting the cumulative CO₂ production after a sufficiently long incubation period (Heitkötter et al., 2017a; Meyer et al., 2017, 2018).

The dynamics of C mineralization in subsoils were largely controlled by nutrient availability, notably N. The supplement of N (Glu + PS + CN10) in addition to P and S (Glu + PS) increased the cumulative C losses by 5–30 fold (increasing with soil depth), whereas the supplement of P and S (Glu + PS + CN10) in addition to N (Glu + CN10) increased the cumulative C losses merely by ~20%. This substantiates the potential importance of N limitation for C mineralization in subsoils (Fierer et al., 2003; Heitkötter et al., 2017b; Meyer et al., 2018).

Nitrogen limitation in subsoil was also reflected by microbial processes at the level below integral CO₂ production. Addition of glucose and N increased β-glucosidase activity, which was positively correlated to the maximum CO₂ production rate. Moreover, microbial metabolic diversity of CSU was mainly related to the absence or presence of added N. Collectively, these results indicated that N addition plays a critical role in shaping microbial physiological responses related to turnover of labile C in subsoils. Previously, such links between N availability and microbial responses have mainly been traced in topsoils (Averill and Waring, 2017; Chen et al., 2017). Yet, in a study with chemically divergent root biomasses, Z. Liang et al. (unpublished data) likewise found that root N concentration affected root C mineralization and microbial dynamics in subsoils and that mineralization of residual root C was enhanced by added mineral N.

In the absence of P and S, treatments with glucose and N showed prolonged lag-phases before onset of stimulated mineralization and/or prolonged turnover time of glucose (Fig. 1), which could be related to retarded growth of microorganisms dependent on the production of exopolymers or exoenzymes for P and S mining (Fontaine et al., 2003; Heitkötter et al., 2017a). For example, as a starvation response to sulfate, soil microorganisms have previously been shown to increase the production of sulfonates and sulfates, which catalyse desulfonation of carbon-bonded sulfur and sulfate esters (Fitzgerald, 1976; Kertesz, 1999).

4.2. Nutrient stoichiometry and carbon use efficiency in subsoils

Added glucose was fully depleted in subsoils when N limitation was alleviated. According to the stoichiometric decomposition theory (e.g., Hessen et al., 2004), relatively more C may be incorporated into microbial biomass, rather than being respired to CO₂, when nutrient availability meets the microbial demand (Hessen et al., 2004; Sinsabaugh et al., 2013). Therefore, it was expected that CO₂ production would decrease with increasing and balanced nutrient availability in subsoil. However, the results indicated that the CO₂ production was on average 17% higher in the nutrient balanced Glu + PS + CN10 and Glu + PS + CN20 treatments than in the relatively nutrient-poorer
Glu + CN10 or Glu + PS + CN60 treatments (Fig. 2a). This aligns with findings by Creamer et al. (2014) and C.A. Creamer et al. (2016), who showed that glucose-derived CO2 production increased significantly with nutrient addition in both sandy and clayey topsoils. In our study it could be hypothesized that microbial biomass derived from glucose in the nutrient balanced treatments was higher at an earlier stage of incubation, but that the biomass was subsequently decomposed eventually releasing CO2 (Van Veen et al., 1985). Alternatively, the results could be linked to development of microbial community structures with different C use efficiency under different nutrient conditions, for example related to increased C investment in production and release of extracellular compounds for mining of deficient nutrients (Kertesz, 1999; Fontaine et al., 2003; Sinsabaugh et al., 2013; Chen et al., 2014). Although speculative, these mechanisms would align with comparatively lower CO2 production in the relatively nutrient poorer Glu + CN10 and Glu + PS + CN60 treatments in the subsoils. Yet, with the present data, no clear differentiation could be made between effects related microbial growth and C mineralization.

4.3. Nutrient availability and subsoil carbon sequestration

Enhancing subsoil organic C storage is suggested to have importance for climate change mitigation (Lorenz and Lal, 2005; Kell, 2011; Lynch and Wojciechowski, 2015). However, labile organic C entering subsoils, such as root exudates by deep rooted crops, may eventually result in CO2 efflux due to mineralization by microorganisms. Still, as demonstrated here, and substantiated in other studies (Fierer et al., 2003; Heitkötter et al., 2017b; Meyer et al., 2018), subsoil N limitation of microbial activity and C turnover may allow prolonged persistence of easily decomposable C. Since low N concentration is a common property in many subsoil ecosystems (Fierer et al., 2003; Jia et al., 2017; Tian et al., 2016), this could be a general mechanism related to C retention in subsoils. Nevertheless, stabilization of SOC on decadal to centurial time scales is believed largely to be linked to physical protection of remains of C compounds resulting from microbial growth and anabolism (Cotrufo et al., 2013; Liang et al., 2017). In this way, stabilization of SOC may paradoxically depend on CO2 losses, which result from the use of organic C as electron donor in the energy metabolism coupled to anabolism in aerobic and anaerobic heterotrophs.

Kirkby et al. (2013, 2014) showed that combined supplementary nutrients (N, P and S) increased the formation of stable SOC when fresh C was incorporated into topsoils from varying agro-ecological regions in Australia. It was argued that the conservative use of fertilizers in modern farming systems may unintentionally limit the supply of nutrients for microbial growth and stable C formation, which could explain why SOC in some agricultural soils increases less than expected from the amounts of returned C-rich residues (Kirkby et al., 2014). Thus, to increase stable C formation, Kirkby et al. (2013) suggested that nutrients could be added to stubbles before their post-harvest incorporation to soil according to the C:N:P:S stoichiometry of humus. Whereas such nutrient addition could increase subsoil C stabilization, our study additionally indicated that a moderately higher content of retained C could form under relatively nutrient-poor as compared to more nutrient balanced conditions. This could potentially be attributed to microbial adaptation and responses to conditions not fully alleviating nutrient limitation (discussed in Section 4.2), with extracellular C investments eventually contributing to the stable C pool. However, better understanding of the mechanisms regulating the fate of subsoil C in response to nutrient stoichiometry should be pursued in order to potentially predict the response of subsoil C sequestration for example in relation to anthropogenic addition of nutrients to topsoil. Likewise, future studies should include the use of labeled C substrates to quantify potential priming effects related to nutrient stimulation of subsoil SOC mineralization (Ruzyakov, 2010), which expectedly was low in the present subsoils where the SOC content was only 0.04–0.18%. Such studies should also include soil types with other ranges of clay content and pH, since microbial processes and the stabilization of microbial degradation products may also depend on soil properties. Finally, it should be realized that conclusions from laboratory incubation studies may well indicate potential processes and mechanisms, but may need to be substantiated by studies under in situ soil conditions.

4.4. Effects of nutrient availability on subsoil clay dispersibility

Extracellular organic compounds (e.g., polysaccharides) produced during microbial anabolic processes may bond soil minerals into differently sized organo-mineral complexes, which contribute to improved soil structure (Degens, 1997). Visually, soil samples after the 42 days incubation period showed signs of varying soil aggregation depending on the nutrient treatments. Therefore, we screened the different nutrient treatments for their potential to improve soil structure (tested as reduced clay dispersibility). The results showed a markedly lower clay dispersibility for the Glu + CN10 treatment than for the other treatments. At first, this indicated that presence of N, but concurrent lack of P and S, triggered a microbial response related to mechanisms of clay stabilization, such as production of exudates for P and S mineralizing (Mooshammer et al., 2014; Richardson et al., 2011). Yet, a control experiment challenged this hypothesis as the same Glu + CN10 treatment resulted in very low clay dispersibility just after 5 h of incubation, thus pointing at chemical rather than biological mechanisms. This was confirmed when increasing levels of KNO3 (10–500 μg N g−1 soil) was added to subsoil that was immediately assayed for clay dispersibility; compared to reference treatments remarkable reductions in clay dispersibility of 78% and 96% were observed already for KNO3 levels of 10 and 50 μg N g−1 soil, respectively (Z. Liang, unpublished data). Whereas this soil physical response may warrant further documentation, it was believed to result from interaction between NO3− and clay dispersibility. This could also explain why the response was seen both initially and after 42 days of incubation with the subsoil Glu + CN10 treatments (where NO3− may not have been depleted due to lack of P and S), but on the other hand the response was seen only initially (and not after 42 days) for the Glu + PS + CN10 treatment, where NO3− was expectedly as was depleted during the 42 days incubation in accordance with the extensive glucose mineralization (Figs. 6 and S4). It remained uncertain, therefore, to what extent the N-stimulated microbial activity in the present study contributed to soil structural changes in the subsoil. Hence, we encourage further studies focusing on the interactions between biochemical and physical mechanisms of subsoil C stabilization.

5. Conclusions

This work focused on the fate and effects of labile C in a temperate sandy loam subsoil in relation to different nutrient availability of N, P, and S. Our results from laboratory incubations suggest that N availability is a key factor controlling labile subsoil C mineralization to CO2. We have shown that glucose amendments with P and S, but deficient in N, resulted in weak stimulation of subsoil C mineralization and subsequent chemical recovery of 59–92% of added glucose even after 42 days. Yet, when N was added together with P and S, the CO2 production significantly increased and glucose was fully depleted. Analysis of microbial responses to subsoil C and nutrient availability substantiated that increased N availability was linked to increased enzyme activity and increased microbial metabolic diversity. Future studies should substantiate the role of nutrient availability for dynamics of subsoil microbial processes (e.g., related to production of extracellular exudates) and the resulting change in soil structure that may contribute to long-term subsoil C sequestration.
