Nitrous oxide (N₂O) and methane (CH₄) are greenhouse gases influencing on global warming and destruction of ozone layer (Houghton et al., 2001; Crutzen, 1981). The application of livestock manure and mineral fertilisers is an important source of greenhouse gases in agriculture (Bouwman, 1996; Mosier et al, 1998). The emissions of N₂O originate from nitrification and denitrification processes which are strongly influenced by soil temperature, moisture, pH and availability of soluble organic matter (Granli & Bøckman, 1994). Currently, there is lack of knowledge about the effect of different application techniques on fluxes from agricultural soils.

In this study, the effects of different application techniques on emissions of these gases from a barley field were compared. During a five-month period, slurry injection in combination with sowing produced the most N₂O, cumulative N₂O flux (□SE) being 1100□169 g N ha⁻¹. When slurry was injected and mineral fertiliser placed in combination with sowing, the cumulative N₂O emissions were 660□70 g N ha⁻¹. Cumulative N₂O flux was 400□37 g N ha⁻¹ from slurry incorporated one hour after band spreading followed by combined placement of mineral fertiliser and sowing. N₂O emissions were the lowest (290□27 g N ha⁻¹) when mineral fertiliser without slurry was placed in combination with sowing. The proportion of applied N lost as N₂O during the five-month period was the highest (0.8%) in the treatment where only slurry was injected, and the lowest (0.3%), when mineral fertiliser was placed. Cumulative CH₄ fluxes ranged from -290 g ha⁻¹ to 50 g ha⁻¹ in the treatments and no significant effect of the application technique was detected. The results suggest that separate emission factors should be developed for N₂O emissions resulting from different application techniques.
